The instability in a pressure-driven core-annular flow of two miscible fluids having the same densities, but different viscosities in the presence of two scalars diffusing at different rates (double-diffusive effect) is investigated via linear stability analysis and axisymmetric direct numerical simulation. It is found that the double-diffusive flow in a cylindrical pipe exhibits strikingly different stability characteristics compared to the double-diffusive flow in a planar channel and the equivalent single-component flow (wherein viscosity stratification is achieved due to the variation of one scalar) in a cylindrical pipe. The flow which is stable in the context of single-component systems, now becomes unstable in the presence of two scalars diffusing at different rates. It is shown that increasing the diffusivity ratio enhances the instability. In contrast to the single fluid flow through a pipe (the Hagen-Poiseuille flow), the faster growing axisymmetric eigenmode is found to be more unstable than the corresponding corkscrew mode for the parameter values considered, for which the equivalent single-component flow is stable to both the axisymmetric and corkscrew modes. Unlike single-component flows of two miscible fluids in a cylindrical pipe, it is shown that the diffusivity and the radial location of the mixed layer have non-monotonic influences on the instability characteristics. An attempt is made to understand the underlying mechanism of this instability by conducting the energy budget and inviscid stability analyses. The investigation of linear instability due to the double-diffusive phenomenon is extended to the nonlinear regime via axisymmetric direct numerical simulations. It is found that in the nonlinear regime the flow becomes unstable in the presence of double-diffusive effect, which is consistent with the predictions of linear stability theory. A new type of instability pattern of an elliptical shape is observed in the nonlinear simulations in the presence of double-diffusive effect.

Key words: Laminar flow, Double-diffusive effect, Core-annular flow, Linear stability, Direct numerical simulation

1. Introduction

Instabilities in core-annular flows of two miscible fluids (i.e. consist of one fluid in the core and the other fluid in the annular region of a pipe) have been extensively studied due to their relevance in many industrial applications, e.g transportation of crude oil in pipelines, polymer deposition and extrusion, food processing industries, etc (Homsy 1987; Selvam *et al.* 2007; Govindarajan & Sahu 2014). Viscosity stratified flows can also be observed in natural phenomena, e.g. turbidity current (Nasr-Azadani & Meiburg 2014). In these flow systems, viscosity-stratification is achieved due to the presence of single

[†] Email address for correspondence: ksahu@iith.ac.in

scalar or multiple scalars diffusing at different rates, such as concentration of a species, temperature etc. Here, the former and the latter systems are termed as single-component (SC) and double-diffusive (DD) flows, respectively. More explicitly, SC systems are the flows having a pure solvent and a solution of the same solvent containing a species at a particular concentration. On the other hand, when the viscosity stratification results from not one, but two species of different diffusivities, the systems are referred to as double-diffusive (DD) systems.

There have been many studies of buoyancy-driven flows in which double diffusion affects density (Turner 1974; Taghavi *et al.* 2009) but far fewer studies of pressure-driven flows in which double diffusion affects viscosity (see e.g. Mishra *et al.* (2010); Sahu (2013)). The instabilities associated with density-stratified systems are not discussed further, as the focus of the present study is to isolate the effect of viscosity-stratification due to the presence of two scalars diffusing at different rates, and to investigate the instabilities in an otherwise stable core-annular pipe flow. This problem has not been investigated yet to the best of the author's knowledge.

It is well known that flow through a circular pipe is very different from flow through a planar channel even in constant viscosity systems. Classical linear stability analysis has shown that channel flow of a constant viscosity fluid is linearly unstable for Reynolds number, $Re > 5772.2$, whereas the Hagen-Poiseuille pipe flow is stable for any Re (Schmid & Henningson 2001).

Let us now discuss what happens in single-component (SC) three-layer flows of two miscible fluids in planar channels. By conducting linear stability analysis in a three-layer channel flow, Govindarajan (2004); Ranganathan & Govindarajan (2001) showed that laminar flow becomes unstable when the near wall fluid is more viscous than the fluid in the central region of the channel. In addition to the Tollmien-Schlichting (TS) mode, a new mode of instability was found at low Reynolds number (Re) and high diffusivity, when the critical layer (a location where the axial velocity is equal to the phase speed of dominant mode) overlap with the mixed layer of varying viscosity. On the other hand, a large stabilization occurs in the opposite configuration, when the less viscous fluid is placed at the near wall region (Govindarajan 2004). In the unstable configuration by conducting a linear stability analysis, Sahu *et al.* (2009) found that the flow is absolutely unstable under certain parameter ranges, which in turn takes the flow towards a transitional state via a nonlinear mechanism.

In the case of core-annular miscible SC flows in cylindrical pipes, several authors (Lajeunesse *et al.* 1999, 1997; Scoffoni *et al.* 2001; Selvam *et al.* 2009) have examined the development of axisymmetric and corkscrew patterns. Similar instability patterns were also observed in the experiment of d'Olce *et al.* (2008) in the case of neutrally buoyant, miscible core-annular flows in horizontal pipes at high Schmidt and Reynolds numbers. Selvam *et al.* (2007) conducted linear stability analysis for a core-annular flow in a pipe, and showed that beyond a critical viscosity ratio, the flow is unstable even when the less viscous fluid is at the wall, in contrast to immiscible lubricated pipelining (Joseph *et al.* 1997) and to miscible planar channel flows (Govindarajan 2004; Sahu *et al.* 2009; Malik & Hooper 2005) which are stable in this configuration. Selvam *et al.* (2007) also showed that the axisymmetric (corkscrew) mode is dominant if the pipe core is occupied with the more (less) viscous fluid. This is in contrast with the single fluid pipe flow (the Hagen-Poiseuille flow), for which the corkscrew mode is always the least stable one.

The investigations discussed so far are for SC systems. One objective of the present study is to identify the differences between the DD systems with their SC counterparts. The instability due to the DD effect in miscible flows of two fluids having different viscosities has received comparatively less attention than that received by SC systems. By

conducting linear stability analysis, Sahu & Govindarajan (2011) investigated the instability associated with DD phenomenon in a three-layer channel configuration, wherein viscosity decreases towards the wall. As discussed above, this is a stable configuration in the context of SC flows as the less viscous fluid present in the near wall region essentially acts as a lubricating fluid (Ranganathan & Govindarajan 2001). Their results show the existence of an unstable DD mode at low Re (about 100) in this classically stable configuration (Sahu & Govindarajan 2011). The DD system is observed to exhibit instability characteristics which are fundamentally different from those shown by SC systems. Their investigation clearly demonstrates the significance of viscosity stratification in a double-diffusive three-layer channel flow. In a similar system with DD effect, Sahu & Govindarajan (2012) demonstrated the appearance of a rapidly growing absolute instability, which is only convectively unstable without the presence of DD phenomenon. The instabilities due to the influence of DD effect were also observed in other flow systems, e.g. displacement of a highly viscous fluid by a less viscous one in porous media (Mishra *et al.* 2010; Swernath & Pushpavanam 2007), Hele-Shaw cell (Pritchard 2009), and in pressure-driven flow in a channel (Mishra *et al.* 2012). A review of instabilities associated with DD effect in various flow configurations can be found in Govindarajan & Sahu (2014).

Recently, Bhagat *et al.* (2016) numerically investigated displacement flow of a less viscous fluid initially occupying an entire pipe by a highly viscous fluid injected at the inlet, in the presence of DD effect. They found instability due to the DD phenomenon in a classically stable configuration in the context of SC flows (Saffman & Taylor 1958). The present work differs from that of Bhagat *et al.* (2016) in two ways: (i) the geometry considered in the present study is a core-annular configuration, whereas Bhagat *et al.* (2016) studied a displacement flow of one fluid by another one, (ii) they performed numerical simulations of a displacement flow in an extended pipe, on the other hand, the objective of the present work is to study instabilities associated with a core-annular flow in linear and nonlinear regimes via linear stability analysis and direct numerical simulations.

As the above brief review shows, all the previous work carried out on the DD effect has so far been for planar channels (except the recent study of Bhagat *et al.* (2016)) although cylindrical geometries are frequently encountered in industrial applications. Hence, the main goal of the present work is to establish the differences between viscosity-stratified core-annular flows with their planar counterparts in the presence of the DD effect. In the present work, a core-annular pipe flow in the presence of the DD effect is investigated via a temporal linear analysis and axisymmetric direct numerical simulations. It is shown that the flow which is stable in the context of SC systems, now becomes unstable in the presence of the DD effect. Increasing the diffusivity ratio of the faster and the slower diffusing scalars enhances the instability. It is shown that the faster-growing axisymmetric mode is more unstable than the corresponding corkscrew mode for the parameter values considered in this work, whereas the equivalent SC flows are stable to all the modes. The diffusion and the radial location of the mixed layer are found to have non-monotonic effects on the instability characteristics. An energy budget analysis and inviscid stability theory are conducted in order to understand the underlying mechanism of the instability in the DD pipe flow. The study of linear instability due to the DD phenomenon is extended to the nonlinear regime via direct numerical simulations.

The rest of this paper is organised as follows. The problem is formulated and the governing linear stability equations are derived in Section 2. The results obtained from the linear stability analysis are discussed in Section 3, wherein a parametric study is conducted to investigate the effects of diffusivity ratio, location and thickness of the

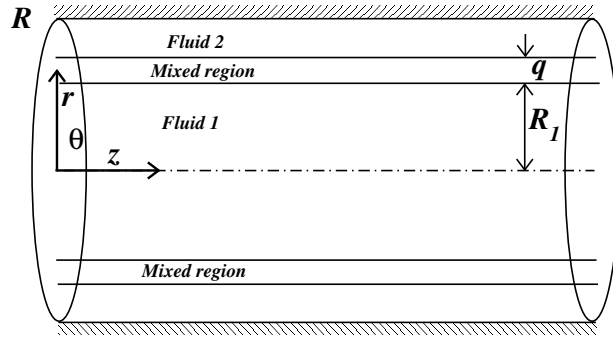

Figure 1: Schematic of the flow configuration considered. Fluids ‘1’ and ‘2’ occupy the core ($0 \leq r \leq R_1$) and annular ($R_1 + q < r < R$) regions of the pipe, respectively. The fluids are separated by a mixed layer of uniform thickness q .

mixed layer. The results obtained from the direct numerical simulations are presented in Section 4. Concluding remarks are provided in Section 5.

2. Formulation

The linear stability characteristics and direct numerical simulations of a pressure-driven core-annular flow of two miscible fluids consisting of two scalars diffusing at different rates in a rigid and impermeable pipe of radius R is considered. A schematic diagram of the system is shown in Fig. 1. The fluids are Newtonian and incompressible of equal densities and different viscosities. A cylindrical coordinate system (r, θ, z) , where r , θ and z denote the radial, the azimuthal and the axial coordinates, respectively, is used. The core fluid of viscosity μ_1 (fluid ‘1’), which is located in the region $0 \leq r \leq R_1$, contains the slower and the faster diffusing scalars, S and F respectively, in quantities S_1 and F_1 . Another fluid of viscosity μ_2 (fluid ‘2’), containing the slower and the faster diffusing scalars in quantity S_2 and F_2 , occupies the annular region of the pipe ($R_1 + q < r < R$). The fluids are separated by a mixed layer of uniform thickness q (Selvam *et al.* 2007; Sahu & Govindarajan 2011). The parallel flow approximation is employed in prescribing the thickness q to be uniform. The diffusion of the two fluids is proportional to the inverse of the Péclet number ($Pe = ScRe$); Re and Sc are Reynolds and Schmidt numbers defined below. As the minimum Reynolds numbers considered in this study is $O(10^2)$, the parallel flow approximation is justified unless $Sc \ll 1$.

The dynamic viscosity, μ is assumed to be an exponential function of the concentration of the scalars:

$$\mu = \mu_1 \exp \left[R_s \left(\frac{S - S_1}{S_2 - S_1} \right) + R_f \left(\frac{F - F_1}{F_2 - F_1} \right) \right], \quad (2.1)$$

where $R_s (\equiv (S_2 - S_1)d(\ln\mu)/dS)$ and $R_f (\equiv (F_2 - F_1)d(\ln\mu)/dF)$ are the log-mobility ratios of the slower and faster diffusing scalars, respectively.

The flow dynamics are governed by the incompressible form of continuity and Navier-

Stokes equations along with the convection-diffusion equations for both the scalars:

$$\nabla \cdot \mathbf{u} = 0, \quad (2.2)$$

$$\rho \left[\frac{\partial \mathbf{u}}{\partial t} + \mathbf{u} \cdot \nabla \mathbf{u} \right] = -\nabla p + \nabla \cdot [\mu(\nabla \mathbf{u} + \nabla \mathbf{u}^T)], \quad (2.3)$$

$$\frac{\partial S}{\partial t} + \mathbf{u} \cdot \nabla S = \mathcal{D}_s \nabla^2 S, \quad (2.4)$$

$$\frac{\partial F}{\partial t} + \mathbf{u} \cdot \nabla F = \mathcal{D}_f \nabla^2 F, \quad (2.5)$$

where $\mathbf{u} \equiv (u_{rT}, u_{\theta T}, u_{zT})$ is the velocity vector, and u_{rT} , $u_{\theta T}$ and u_{zT} are the velocity components in the radial, the azimuthal and the axial directions, respectively, t is time and p denotes pressure. \mathcal{D}_s and \mathcal{D}_f are the diffusion coefficients of the slower and the faster diffusing scalars, respectively. Thus by definition $\mathcal{D}_f > \mathcal{D}_s$, and $\delta \equiv \mathcal{D}_f/\mathcal{D}_s$ is greater than or equal to one; $\delta = 1$ represents a system having scalars of equal diffusion coefficients.

Eqs. (2.1)-(2.2) are nondimensionalised using the radius of the pipe (R) as the length scale and $V \equiv Q/\pi R^2$ as the velocity scale, where Q denotes the volumetric flow rate. The following scaling is employed to render the governing equations dimensionless:

$$(r, z, q, R_1) = R (\tilde{r}, \tilde{z}, \tilde{q}, \tilde{R}_1), \quad t = \frac{R}{V} \tilde{t}, \quad (u_{rT}, u_{\theta T}, u_{zT}) = V (\tilde{u}_{rT}, \tilde{u}_{\theta T}, \tilde{u}_{zT}), \quad p = \rho V^2 \tilde{p},$$

$$\mu = \tilde{\mu} \mu_1, \quad \tilde{s} = \frac{S - S_1}{S_2 - S_1}, \quad \tilde{f} = \frac{F - F_1}{F_2 - F_1}, \quad (2.6)$$

where tildes designate dimensionless quantities and ρ is the constant density. After dropping the tildes decoration, the dimensionless governing equations are given by

$$\nabla \cdot \mathbf{u} = 0, \quad (2.7)$$

$$\left[\frac{\partial \mathbf{u}}{\partial t} + \mathbf{u} \cdot \nabla \mathbf{u} \right] = -\nabla p + \frac{1}{Re} \nabla \cdot [\mu(\nabla \mathbf{u} + \nabla \mathbf{u}^T)], \quad (2.8)$$

$$\frac{\partial s}{\partial t} + \mathbf{u} \cdot \nabla s = \frac{1}{ReSc} \nabla^2 s, \quad (2.9)$$

$$\frac{\partial f}{\partial t} + \mathbf{u} \cdot \nabla f = \frac{\delta}{ReSc} \nabla^2 f, \quad (2.10)$$

where $Re \equiv \rho V R / \mu_1$, $Sc \equiv \mu_1 / \rho \mathcal{D}_s$ are the Reynolds number and Schmidt numbers, respectively, which are defined based on the slower diffusing scalar. Thus, the effective Schmidt number of the faster diffusing fluid is Sc/δ .

The dimensionless viscosity, μ is given by

$$\mu = \exp(R_s s + R_f f). \quad (2.11)$$

Here, $R_s + R_f > 0 (< 0)$ represents a configuration when the annular fluid is more (less) viscous than the core fluid. The focus of the present study is to investigate the instability of systems which are stable in the context of single component flows.

2.1. Linear stability analysis

2.1.1. Basic state

The basic state whose linear stability characteristics will be analyzed, corresponds to a steady, parallel, fully-developed flow, i.e. $U_r = U_\theta = 0$; $U_z = U_z(r)$, and P is linear in

z. This is obtained by solving the steady, fully-developed version of Eq. (2.8), i.e.,

$$\frac{1}{r} \frac{\partial}{\partial r} \left[r \mu_0 \frac{\partial U_z}{\partial r} \right] = \frac{dP}{dz} Re, \quad (2.12)$$

subject to the no-slip and the symmetric boundary conditions at the pipe wall and the centerline of the channel, respectively. The dimensionless pressure gradient dP/dz is fixed by using $\int_0^1 U_z r dr = 1$. Here $\mu_0 = e^{(R_s s_0 + R_f f_0)}$. The basic state quantities are designated by upper-case letters for the flow variables, and by the subscript 0 for viscosity, s and f . In order to make the concentration of the scalars continuous up to the second derivative at $r = R_1$ and $r = R_1 + q$, the scalars s_0 and f_0 are chosen to be fifth order polynomials in the mixed layer (Sahu & Govindarajan 2011):

$$\begin{aligned} s_0 = f_0 = 0, & \quad 0 \leq r \leq R_1, \\ s_0 = f_0 = \sum_{i=1}^6 a_i r^{i-1}, & \quad R_1 \leq r \leq R_1 + q, \\ s_0 = f_0 = 1, & \quad R_1 + q \leq r \leq 1, \end{aligned} \quad (2.13)$$

where a_i ($i = 1, 6$) are given by

$$\begin{aligned} a_1 = -\frac{R_1^3}{q^5} (6R_1^2 + 15R_1q + 10q^2), \quad a_2 = \frac{30R_1^2}{q^5} (R_1 + q)^2, \\ a_3 = -\frac{30R_1}{q^5} (R_1 + q)(2R_1 + q), \quad a_4 = \frac{10}{q^5} (6R_1^2 + 6R_1q + q^2), \\ a_5 = -\frac{15}{q^5} (2R_1 + q) \quad \text{and} \quad a_6 = \frac{6}{q^5}. \end{aligned} \quad (2.14)$$

It has been confirmed that the other sufficiently smooth profiles, like the one used by Selvam *et al.* (2007):

$$s_0 = f_0 = 0.5 + 0.5 \operatorname{erf} \left[\frac{r - R_1 - 0.5q}{0.25q} \right], \quad (2.15)$$

also gives results practically indistinguishable from those presented here. The validity of the basic state considered in this study is discussed in Appendix 3.

Typical basic state profiles of axial velocity (U_z) and viscosity (μ_0) are shown for different values of R_f in Fig. 2(a) and (b), respectively. The rest of the parameters are chosen as $R_1 = 0.7$, $q = 0.1$ and $R_s = 1$. In Fig. 2(a), it can be seen that the basic state axial velocity at the mixed region increases with decreasing the value of R_f . It is also seen that for $R_f = -0.9$ and -1.1 , the annular fluid is respectively more and less viscous than the fluid occupying the core of the pipe; $R_f = -1$ means that both fluids are of equal viscosities (single-component (SC) system), as $R_s = 1$. In three-layer SC channel flows, it is well known that when the near wall fluid is less viscous, the velocity profile goes away from the inflectional profile (i.e. profile with $U_z'' = 0$) and thus has a stabilising influence (Govindarajan 2004). However, for pipe flows, Selvam *et al.* (2007) showed that an axisymmetric mode becomes unstable above a critical viscosity ratio even when the annular fluid is less viscous. These aspects will be discussed again in the following section.

2.1.2. Linear stability equations

We investigate the temporal stability of the basic flow given by Eqs (2.12)-(2.13) to infinitesimal perturbations using a normal mode analysis by expressing each flow variable

Figure 2: Basic state profiles of (a) axial velocity (b) viscosity, for different values of R_f . The rest of the parameter values are $R_1 = 0.7$, $q = 0.1$ and $R_s = 1$.

as a sum of the basic state and a time-dependent perturbation (designated by a hat):

$$(u_{rT}, u_{\theta T}, u_{zT}, p, s, f)(r, \theta, z, t) = (0, 0, U_z(r), P, s_0(r), f_0(r)) + (\hat{u}_r, \hat{u}_\theta, \hat{u}_z, \hat{p}, \hat{s}, \hat{f})(r) e^{i(\alpha z + \beta \theta - \omega t)}, \quad (2.16)$$

where $i \equiv \sqrt{-1}$, α , β and $\omega (\equiv \alpha c)$ are the wavenumbers in the axial and the azimuthal directions (real), and the frequency (complex) of the perturbation, respectively, wherein $c (\equiv c_r + ic_i)$ is the phase speed of the perturbation. The subscripts r and i represent the real and imaginary parts, respectively. Here, a given mode is unstable if $\omega_i > 0$, stable if $\omega_i < 0$ and neutrally stable if $\omega_i = 0$. The perturbation viscosity is given by: $\hat{\mu} = \frac{\partial \mu_0}{\partial s_0} \hat{s} + \frac{\partial \mu_0}{\partial f_0} \hat{f}$. Following the standard procedure (Schmid & Henningson 2001): (i) substitution of Eq. (2.16) into Eqs. (2.7)-(2.10), (ii) subtraction of the basic state equations, and (iii) linearization and elimination of the pressure perturbation, we obtained the following linear stability equations (suppressing the hat notations):

$$u_r' + \frac{u_r}{r} + \frac{\beta u_\theta}{r} + \alpha u_z = 0, \quad (2.17)$$

$$-\omega u_r + \alpha u_r U_z = p' - \frac{i}{Re} \left[\mu_0 \left\{ u_r'' + \frac{u_r'}{r} - \left(\frac{\beta^2 + 1}{r^2} + \alpha^2 \right) u_r - \frac{2\beta}{r^2} u_\theta \right\} + 2\mu_0' u_r' + \alpha U_z' \mu \right], \quad (2.18)$$

$$-\omega u_\theta + \alpha u_\theta U_z = -\frac{\beta p}{r} - \frac{i\mu_0}{Re} \left\{ u_\theta'' + \frac{u_\theta'}{r} - \left(\frac{\beta^2 + 1}{r^2} + \alpha^2 \right) u_\theta - \frac{2\beta}{r^2} u_r \right\} - \frac{i\mu_0'}{Re} \left[u_\theta' - \frac{u_\theta}{r} - \frac{\beta u_r}{r} \right], \quad (2.19)$$

$$-\omega u_z + U_z' u_r + \alpha U_z u_z = -\alpha p - \frac{i\mu_0}{Re} \left\{ u_z'' + \frac{u_z'}{r} - \left(\frac{\beta^2}{r^2} + \alpha^2 \right) u_z \right\} - \frac{i\mu_0'}{Re} [v_z' - \alpha v_r] - \frac{iU_z'}{Re} \mu' - \frac{i\mu}{Re} \left[U_z'' + \frac{U_z'}{r} \right], \quad (2.20)$$

$$-\omega s + s_0' u_r + \alpha U_z s = -\frac{i}{Re Sc} \left\{ s'' + \frac{s'}{r} - \left(\frac{\beta^2}{r^2} + \alpha^2 \right) s \right\}, \quad (2.21)$$

$$-\omega f + f_0' u_r + \alpha U_z f = -\frac{i\delta}{ReSc} \left\{ f'' + \frac{f'}{r} - \left(\frac{\beta^2}{r^2} + \alpha^2 \right) f \right\}, \quad (2.22)$$

where the prime denotes differentiation with respect to r . We confirm that for the no viscosity-stratification case, i.e. by setting $\mu_0 = 1$, these equations reduce to the stability equations for the Hagen-Poiseuille flow (Schmid & Henningson 2001). Solutions of these equations are obtained subject to the following boundary conditions (Selvam *et al.* 2007; Sahu & Govindarajan 2005):

At the centerline of the pipe ($r = 0$), the boundary conditions are

$$v_r = 0, \quad v_\theta = 0, \quad v_z' = 0, \quad p' = 0, \quad s' = 0 \quad \text{and} \quad f' = 0 \quad \text{for} \quad \beta = 0, \quad (2.23)$$

$$v_r + v_\theta = 0, \quad 2v_r' + v_\theta' = 0, \quad v_z = 0, \quad p = 0, \quad s = 0 \quad \text{and} \quad f = 0 \quad \text{for} \quad \beta = 1, \quad (2.24)$$

$$v_r = 0, \quad v_\theta = 0, \quad v_z = 0, \quad p = 0, \quad s = 0 \quad \text{and} \quad f = 0 \quad \text{for} \quad \beta \geq 2. \quad (2.25)$$

At the pipe wall ($r = 1$), the boundary conditions are

$$v_r = 0, \quad v_\theta = 0, \quad v_z = 0, \quad s' = 0 \quad \text{and} \quad f' = 0, \quad (2.26)$$

for all values of β . Eqs. (2.17)-(2.22) along with the boundary conditions (2.24)-(2.26) constitute an eigenvalue problem, given by

$$\begin{bmatrix} \mathcal{A}_{11} & \mathcal{A}_{12} & 0 & \mathcal{A}_{14} & \mathcal{A}_{15} & \mathcal{A}_{16} \\ \mathcal{A}_{21} & \mathcal{A}_{22} & 0 & \mathcal{A}_{24} & 0 & 0 \\ \mathcal{A}_{31} & 0 & \mathcal{A}_{33} & \mathcal{A}_{34} & \mathcal{A}_{35} & \mathcal{A}_{36} \\ \mathcal{A}_{41} & \mathcal{A}_{42} & \mathcal{A}_{43} & 0 & 0 & 0 \\ \mathcal{A}_{51} & 0 & 0 & 0 & \mathcal{A}_{55} & 0 \\ \mathcal{A}_{61} & 0 & 0 & 0 & 0 & \mathcal{A}_{66} \end{bmatrix} \begin{bmatrix} u_r \\ u_\theta \\ u_z \\ p \\ s \\ f \end{bmatrix} = \omega \begin{bmatrix} \mathcal{B}_{11} & 0 & 0 & 0 & 0 & 0 \\ 0 & \mathcal{B}_{22} & 0 & 0 & 0 & 0 \\ 0 & 0 & \mathcal{B}_{33} & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & \mathcal{B}_{55} & 0 \\ 0 & 0 & 0 & 0 & 0 & \mathcal{B}_{66} \end{bmatrix} \begin{bmatrix} u_r \\ u_\theta \\ u_z \\ p \\ s \\ f \end{bmatrix},$$

where,

$$\mathcal{A}_{11} = \alpha U_z + \frac{i\mu_0}{Re} \left\{ \mathcal{D}^2 + \frac{\mathcal{D}}{r} - \left(\frac{\beta^2 + 1}{r^2} + \alpha^2 \right) \right\} + \frac{2i\mu_0'}{Re} \mathcal{D}, \quad \mathcal{A}_{12} = -\frac{2i\beta\mu_0}{r^2 Re}, \quad \mathcal{A}_{14} = -\mathcal{D},$$

$$\mathcal{A}_{15} = \frac{iU_z' \alpha}{R} \mu_0 R_s, \quad \mathcal{A}_{16} = \frac{iU_z' \alpha}{R} \mu_0 R_f, \quad \mathcal{A}_{21} = -\frac{2i\beta\mu_0}{r^2 Re} - \frac{i\beta\mu_0'}{r Re},$$

$$\mathcal{A}_{22} = \alpha U_z + \frac{i\mu_0}{Re} \left\{ \mathcal{D}^2 + \frac{\mathcal{D}}{r} - \left(\frac{\beta^2 + 1}{r^2} + \alpha^2 \right) \right\} + \frac{i\mu_0'}{Re} \left(\mathcal{D} - \frac{1}{r} \right), \quad \mathcal{A}_{24} = \frac{\beta}{r},$$

$$\mathcal{A}_{31} = U_z' - \frac{i\mu_0' \alpha}{Re}, \quad \mathcal{A}_{33} = \alpha U_z + \frac{i\mu_0}{Re} \left\{ \mathcal{D}^2 + \frac{\mathcal{D}}{r} - \left(\frac{\beta^2}{r^2} + \alpha^2 \right) \right\} + \frac{i\mu_0'}{Re} \mathcal{D}, \quad \mathcal{A}_{34} = \alpha,$$

$$\mathcal{A}_{35} = \frac{iU_z'}{Re} (R_s \mu_0 + R_s \mu_0') + \frac{iR_s \mu_0}{Re} \left(U_z'' + \frac{U_z'}{r} \right),$$

$$\mathcal{A}_{36} = \frac{iU_z'}{Re} (R_f \mu_0 + R_f \mu_0') + \frac{iR_f \mu_0}{Re} \left(U_z'' + \frac{U_z'}{r} \right), \quad \mathcal{A}_{41} = \frac{\mathcal{D}}{r} + 1, \quad \mathcal{A}_{42} = \frac{\beta}{r^2}, \quad \mathcal{A}_{43} = \frac{\alpha}{r},$$

$$\mathcal{A}_{51} = s_0', \quad \mathcal{A}_{55} = \alpha U_z + \frac{i}{ReSc} \left\{ \mathcal{D}^2 + \frac{\mathcal{D}}{r} - \left(\frac{\beta^2}{r^2} + \alpha^2 \right) \right\},$$

$$\mathcal{A}_{61} = f_0', \quad \mathcal{A}_{66} = \alpha U_z + \frac{i\delta}{ReSc} \left\{ \mathcal{D}^2 + \frac{\mathcal{D}}{r} - \left(\frac{\beta^2}{r^2} + \alpha^2 \right) \right\},$$

$$\mathcal{B}_{11} = \mathcal{B}_{22} = \mathcal{B}_{23} = \mathcal{B}_{55} = \mathcal{B}_{66} = 1.$$

Here $\mathcal{D} \equiv d/dr$. The domain ($r = [0, 1]$) is discretised using the Chebyshev spectral

Figure 3: Comparison of eigenspectrums for the Hagen-Poiseuille flow obtained using the present code (circles) with those given in Schmid & Henningson (2001) (plus signs) for $Re_{SH} = 2000$. (a) $\alpha = 1$, $\beta = 0$, (b) $\alpha = 0.5$, $\beta = 1$, and (c) $\alpha = 0.25$, $\beta = 2$. Here $Re_{SH} \equiv U_c \rho R / \mu$, where U_c is the centerline velocity and $\mu (\mu_1 = \mu_2)$ is viscosity of fluid, obtained by setting $R_s = R_f = 0$.

collocation method (Canuto *et al.* 1987) and solved using a public domain software, LAPACK. As gradients are large in the mixed region, we require a large number of grid points in this region. For this we use the stretching function (Govindarajan 2004)

$$r_j = \frac{a}{\sinh(br_0)} [\sinh\{(r_c - r_0)b\} + \sinh(br_0)], \quad (2.27)$$

where r_j are the locations of the grid points, a is the mid-point of the mixed layer, r_c is a Chebyshev collocation point, defined as $r_c = 0.5 \cos \left\{ \left[\frac{\pi(j-1)}{(n-1)} \right] + 1 \right\}$, where n is the number of collocation points. In the above equation,

$$r_0 = \frac{0.5}{b} \ln \left[\frac{1 + (e^b - 1)a}{1 + (e^{-b} - 1)a} \right], \quad (2.28)$$

and b is the degree of clustering. We have taken $b = 8$ which gives an accuracy of at least five decimal places in the range of parameters considered.

2.1.3. Validation

In order to validate the predictions of our numerical procedure for the linear stability analysis, we have made detailed comparisons with several published results for single fluid and core-annular flows. In Fig. 3, we compare the eigenspectrums for the Hagen-Poiseuille flow obtained using the present code (by setting $\delta = 1$ and $R_s = R_f = 0$) with those given in Schmid & Henningson (2001) for different values of wavenumbers in the axial and the azimuthal directions, and find excellent agreement. Note that we use the average velocity as a characteristic scale, rather than the centreline velocity, which was used by Schmid & Henningson (2001). The present Reynolds number and phase speed are related with those of Schmid & Henningson (2001) (designated by subscript SH) as $Re = 2Re_{SH}$ and $c = 2c_{SH}$. Excellent agreement is also found (not shown) with the stability analysis of SC core-annular flow through a straight pipe by Selvam *et al.* (2007). The results obtained in the configurations which are stable in the context of equivalent SC flows, as reported by Selvam *et al.* (2007), but are unstable in the presence of DD effect, are discussed below.

3. Results from the linear stability analysis

In order to contrast the instability characteristics due to the double-diffusive effect with the equivalent SC system, the variation of maximum growth rate, $\omega_{i,max}$ with increasing

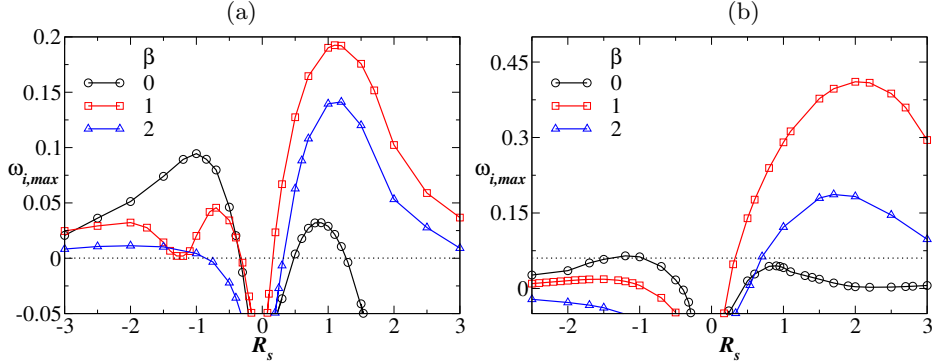

Figure 4: Variation of the maximum growth rate, $\omega_{i,max}$ versus R_s for different values of β in a SC system ($\delta = 1$ and $R_f = 0$): (a) $R_1 = 0.7$ and (b) $R_1 = 0.45$. The rest of the parameter values are $Re = 1000$, $Sc = 10$ and $q = 0.1$.

viscosity ratio (increasing the value of R_s) for a SC system ($\delta = 1$ and $R_f = 0$) is presented in Fig. 4 (a) and (b) for $R_1 = 0.7$ and 0.45 , respectively. The rest of the parameter values are $Re = 1000$, $Sc = 10$ and $q = 0.1$. Three values of azimuthal wavenumber of the perturbation, i.e $\beta = 0, 1$ and 2 are considered for the presentation. The higher modes ($\beta > 2$) are found to be stable for the parameters considered in this study. Here, $R_s > 0$ (< 0) represents a situation when the annular fluid is more (less) viscous than the core fluid. It can be seen in Fig. 4(a) for $R_1 = 0.7$ that when $R_s > 0$, i.e $\mu_2 > \mu_1$, $\beta = 1$ is the most unstable mode giving the highest growth rate, whereas the axisymmetric mode ($\beta = 0$) is the least unstable one; $\beta = 2$ is the intermediate unstable mode for the parameter values considered. A similar observation can be made for $R_1 = 0.45$ (Fig. 4(b)). For $R_s < 0$, when the annular fluid is less viscous than the core fluid ($\mu_2 < \mu_1$), the axisymmetric mode ($\beta = 0$) and swirling mode with $\beta = 1$ give almost the same maximum growth rate upto $R_s \sim -0.5$, but the axisymmetric mode dominates for $R_s < -0.5$. A similar conclusion was reported by Selvam *et al.* (2007). In Fig. 4(b) it can be seen that moving the mixed layer closer to the centerline ($R_1 = 0.45$) significantly increases the maximum growth rate for a positive viscosity ratio ($R_s > 0$), but decreases the maximum growth rate for a negative viscosity ratio ($R_s < 0$); in fact, unlike $R_1 = 0.7$ (Fig 4(a)), for $R_1 = 0.45$ the flow is stable for $R_s < 0$ for this set of parameter values. In the discussion to follow, the linear instability characteristics due to the DD effect ($\delta > 1$) in the parameter regimes where the equivalent SC flow is stable are investigated. In the rest of the work, only the axisymmetric ($\beta = 0$) and corkscrew ($\beta = 1$) modes are considered as higher modes ($\beta > 1$) are less unstable or even stable.

3.1. Effect of δ

The influence of varying the diffusivity ratio of the faster diffusing scalar to that of the slower diffusing scalar, δ is investigated in Fig. 5 (a) and (b) for $R_s = 1$, $R_f = -1.1$, and $R_s = -1.1$, $R_f = 1$, respectively. The remaining parameter values are $Re = 1000$, $Sc = 10$, $R_1 = 0.7$, $q = 0.1$ and $\beta = 1$. From Fig. 4(a), it can be seen that the parameters considered in Fig. 5(a) correspond to a situation when the slower diffusing scalar has a destabilising influence, whereas the faster diffusing scalar is close to a neutrally stable state. The situation is opposite in Fig. 5(b), wherein the faster diffusing scalar has a destabilising influence, whereas the slower diffusing scalar is close to a neutrally stable state. In both the cases, as $R_s + R_f = -0.1$, the net stratification is stabilizing. The equivalent SC system whose diffusivity is the average of \mathcal{D}_s and \mathcal{D}_f , is stable for the

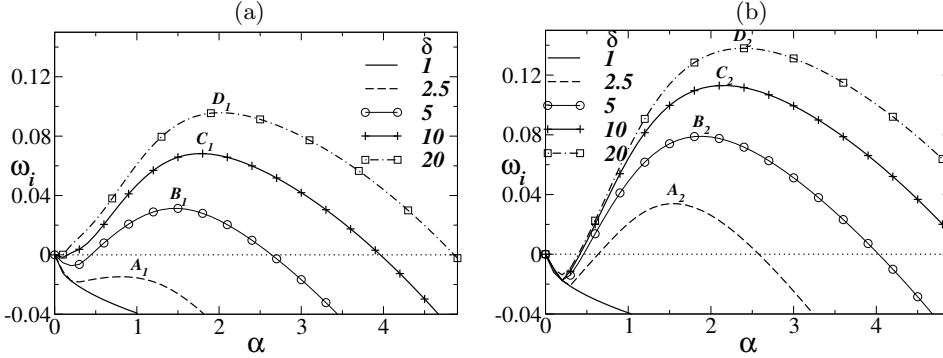

Figure 5: Effect of the relative diffusion rate, δ on the instability growth rate for (a) $R_s = 1$, $R_f = -1.1$, and (b) $R_s = -1.1$, $R_f = 1$. The rest of the parameter values are $Re = 1000$, $Sc = 10$, $R_1 = 0.7$, $q = 0.1$ and $\beta = 1$. The equivalent SC flow ($Sc_{eq} = 2Sc/(\delta + 1)$, $R_s = -0.1$ and $R_f = 0$) is stable ($\omega_i < 0$) for these sets of parameter values. The points A_1 , B_1 , C_1 and D_1 in panel (a) correspond to $\alpha = 1, 1.5, 1.8$ and 2 , respectively. The points A_2 , B_2 , C_2 and D_2 in panel (b) correspond to $\alpha = 1.54, 1.87, 2.14$ and 2.4 , respectively.

parameter values considered. However, the flow becomes unstable in the presence of the DD effect. It can be seen in Fig. 5(a) that the growth rate, ω_i becomes positive for $\delta = 5$, which indicates temporal instability. We also observe that increasing δ increases the growth rate.

Inspection of Fig. 5(b) reveals that the flow becomes unstable for $\delta = 2.5$; a δ value lower than that observed in Fig. 5(a). This is counter-intuitive. In Fig. 5(a), one observes that the scalar f will diffuse away faster, leaving the destabilizing effect of the scalar s , which causes the DD instability. Intuitively less obvious is the existence of the DD instability in figure 5 (b), where the faster diffusing scalar is destabilizing and the slower diffusing scalar is stabilizing. In this case, the scalar having a destabilising influence will diffuse away faster, leaving the stabilising scalar in the flow system. The instabilities seen in Fig. 5(a) and (b) are broadly analogous to the fingering and the oscillatory instabilities, respectively in the DD convection of gravity-driven systems (Turner 1974).

In order to gain insight into the mechanisms underlying the instability which arise due to the DD effect discussed in the foregoing, we carried out an analysis of the energy budget (Selvam *et al.* 2007; Sahu *et al.* 2009) and an inviscid stability analysis (Sahu & Govindarajan 2005), which are outlined in Appendices 1 and 2, respectively.

In the energy budget analysis, the temporal rate of change of the perturbation kinetic energy, $\dot{\mathcal{E}}$ is splitted into several terms based on their contributions to influence $\dot{\mathcal{E}}$, namely, the rate of transfer of energy from the basic flow to the perturbation (\mathcal{P}), rate of viscous

dissipation energy of the perturbation (\mathcal{D}), the rate of energy of the perturbation due to mean viscosity gradients (\mathcal{A}), the rate of perturbation energies associated with the gradient of viscosity perturbation in the radial (\mathcal{B}_r) and axial (\mathcal{B}_z) directions, and the rate of energy due to the gradient of viscosity perturbation (\mathcal{C}) (see Appendix 1 for details). In table 1, the contributions due to these rate of energy transferred terms at points A_1 , B_1 , C_1 and D_1 in Fig. 5(a), which correspond to axial wavenumbers at which the growth rates are maximum for $\delta = 2.5, 5, 10$ and 20 , respectively, are provided. It can be seen that for $\delta = 2.5$ (point A_1) $\dot{\mathcal{E}}$ is negative, indicating that flow is stable. For $\delta \geq 5$, it can be observed that the largest positive contributor to the instability is \mathcal{P} . However, \mathcal{B}_r also contributed to the instability. The perturbation energies associated with mean viscosity gradient (\mathcal{A}), perturbation viscosity gradient in the z -direction (\mathcal{B}_z) and perturbation viscosity itself (\mathcal{C}) are small for all values of δ considered. The viscous dissipation energy \mathcal{D} is negative and thus stabilizing. Inspection of table 1 also reveals that increasing δ increases the positive contributions at much faster rates than the negative contributions.

In order to understand this further, the variation of $\dot{\mathcal{E}}$ and the dominant energy terms, i.e., $-D$, P_d and B_r (defined in Appendix 1) of the most dangerous modes (denoted by A_1 , B_1 , C_1 and D_1 in Fig. 5(a)) in the wall-normal direction are plotted for different values of δ in Fig. 6(a), (b), (c) and (d), respectively. It can be seen that the rate of production due to the transfer of energy from the basic flow to the perturbation (P_d) and gradient of viscosity perturbation in the radial (B_r) is zero everywhere, except in the mixed layer ($0.7 \leq r \leq 0.8$). The rate of viscous dissipation ($-D$), i.e. the rate of energy transfer from the perturbation to the mean flow is negative at the mixed layer and near the pipe wall. However, the combined positive contribution from P_d and B_r is more than the negative viscous dissipation for $\delta > 2.5$ for this set of parameter values. Thus, for $\delta > 2.5$, the perturbation gains energy from the mean flow, which in turn destabilises the flow.

The instability due to the DD effect shown in Fig. 5(b) is intuitively less obvious as in this case, the faster diffusing scalar is more destabilizing than the slower diffusing scalar. Thus, the former will diffuse faster, leaving only the stabilising one (s) in the system. It can be seen in table 2 and Fig. 7 that $\dot{\mathcal{E}}$ is positive even for $\delta = 2.5$, making the flow unstable at a lower diffusivity ratio as compared to that in Fig. 5(a). The contributions from all the energy terms for $R_s = -1.1$ and $R_f = 1$ are also higher than those obtained for $R_s = 1$ and $R_f = -1.1$.

In order to understand the stability behaviour of the flow in the inviscid limit ($Re \rightarrow \infty$), an inviscid analysis is conducted in Appendix 2. Based on this, a pipe flow is inviscidly unstable if the inviscid stability function, $I \equiv U_z'' - U_z'(\alpha^2 r^2 - \beta^2)/r/(\alpha^2 r^2 + \beta^2)$ corresponds to the most dangerous mode changes its sign inside the domain. The radial variations of the inviscid stability function, I for $R_s = 1$, $R_f = -1.1$ and $R_s = -1.1$, $R_f = 1$, with the rest of the parameter values the same as those used to generate Fig. 5, are shown in Fig. 8(a) and (b), respectively. It can be seen that for both sets of parameters, I remains negative for all values of δ . In fact, increasing δ takes away the profile from $I = 0$, which implies that the flow is inviscidly stable for these sets of parameters. It has been checked that this is true even for all other cases studied in this work. As the flow is stable in the limit ($Re \rightarrow \infty$), we will see below that the neutral stability curves are closed curves, unlike several other shear flows, e.g. plane Poiseuille flow.

Next, we investigate the effect of variation of δ on the neutral stability curves for both the axisymmetric ($\beta = 0$) and corkscrew modes ($\beta = 1$) in Fig. 9. The rest of the parameter values are $Sc = 10$, $R_1 = 0.45$, $q = 0.1$, $R_s = 1$ and $R_f = -1.1$. For this figure, R_1 is fixed at 0.45. This selection is motivated from Fig. 4(b), which shows that for $R_1 = 0.45$, when $R_s < 0$, i.e., when the annular fluid is less viscous than the core fluid,

the flow is completely stable for all values of β . Here, the objective is to demonstrate the appearance of the DD instability in the parameter regime where the equivalent SC flow (whose diffusivity is the average of \mathcal{D}_s and \mathcal{D}_f , i.e., $Sc_{eq} = 2Sc/(\delta + 1)$) is stable. In the neutral stability curves shown in Fig. 9(a), the flow is unstable in the region inside the closed curves. The neutral stability curves are closed curves for all values of δ , but complete curves are shown only for $\delta = 5$ and 10. It can also be seen that the unstable region also grows with increase in the value of δ . The zoomed view of Fig. 9(a) is shown in Fig. 9(b), which reveals that increasing δ decreases the critical Reynolds number, Re_{cr} (the minimum value of Re at which the flow becomes linearly unstable). This is quantified in Fig. 9(c), which reveals that Re_{cr} for the axisymmetric mode ($\beta = 0$) is always less

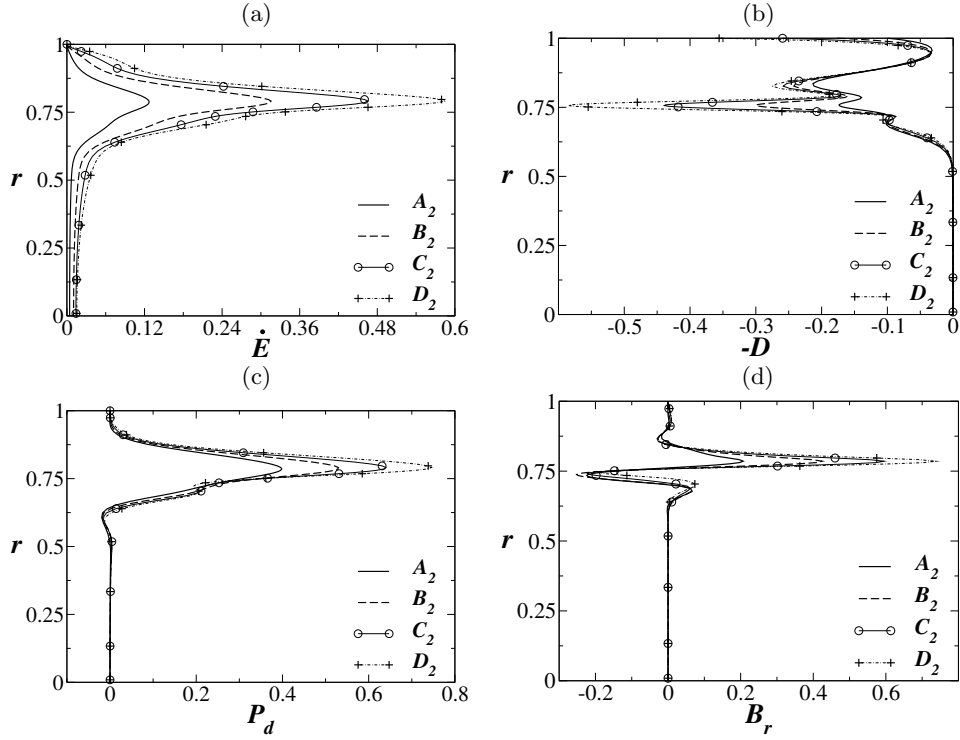

Figure 7: Radial variations of (a) the rate of change of kinetic energy, \dot{E} , (b) the dissipation rate; the negative (D) is shown to help viewing, (c) the production rate, P_d and (d) B_r of the most dangerous modes represented by A_2 , B_2 , C_2 and D_2 in Fig. 5(b) for different values of δ in the wall-normal direction. The rest of the parameter values are the same as those used to generate Fig. 5(b).

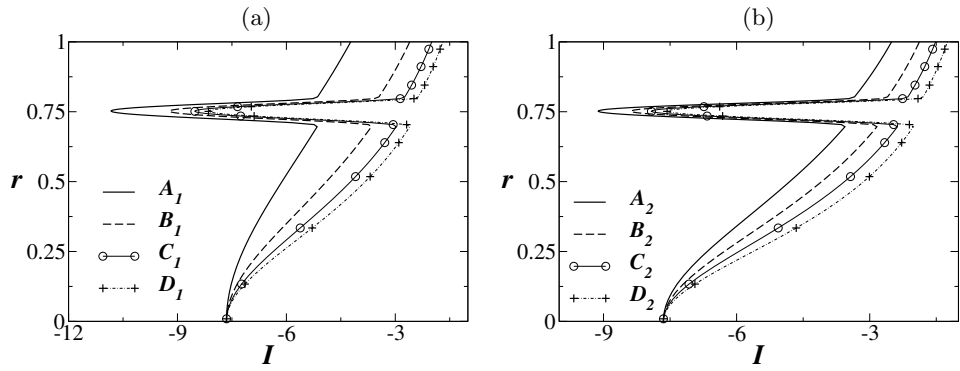

Figure 8: Radial variations of the inviscid instability function, I for the most dangerous modes for (a) $R_s = 1$ and $R_f = -1.1$, (b) $R_s = -1.1$ and $R_f = 1$. The rest of the parameter values are the same as those used to generate Fig. 5

than that of the corkscrew mode ($\beta = 1$), i.e., the faster-growing axisymmetric mode is more unstable than the corresponding corkscrew mode, for this set of parameters.

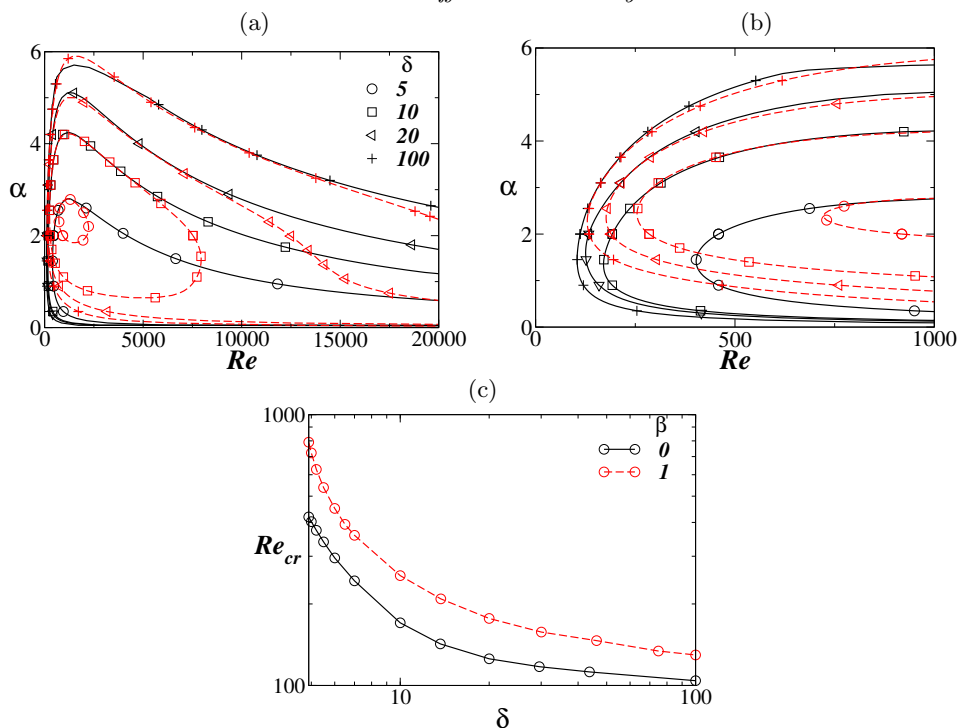

Figure 9: (a) The effect of varying δ on the neutral stability curves (solid lines: $\beta = 0$, dashed lines: $\beta = 1$), (b) zoomed view of panel (a), and (c) Re_{cr} versus δ for both β values. The rest of the parameter values are $Sc = 10$, $R_1 = 0.45$, $q = 0.1$, $R_s = 1$ and $R_f = -1.1$.

3.2. Effect of the radial location of the mixed layer

The effect of radial location of the mixed layer, R_1 on the neutral stability curves for the axisymmetric mode (solid lines) and corkscrew mode (dashed lines) are plotted in Fig. 10(a) and (b) for $R_s = 1$, $R_f = -1.1$ and $R_s = -1.1$, $R_f = 1$, respectively. It can be seen in Fig. 10(a) that for $R_s = 1$ and $R_f = -1.1$, as expected (Selvam *et al.* 2007), the faster-growing axisymmetric mode is more unstable (lower Re_{cr}) than the corresponding corkscrew mode ($\beta = 1$) for $R_1 \leq 0.5$. However, interestingly for $R_1 = 0.7$, it can be seen that the faster-growing corkscrew mode ($\beta = 1$) becomes more unstable than the axisymmetric mode. It is found that this is due to the overlap of the critical layer (the radial location at which the basic state axial velocity, U_z is equal to c_r of the most dangerous mode) with the mixed layer when $\beta = 1$. As discussed by Govindarajan (2004); Talon & Meiburg (2011) for planar flows, the most unstable mode resembles with the interfacial mode of a sharp interface (Yih 1967) in this overlap region. Close inspection also reveals that taking the mixed layer closer to the wall destabilises the flow for $R_s = 1$, $R_f = -1.1$ upto $R_1 = 0.5$, but increasing R_1 further stabilises the flow (see Fig. 10(a)). For $R_s = -1.1$, $R_f = 1$, the critical Reynolds number is almost the same till $R_1 = 0.5$, but has a huge stabilization for $h = 0.7$ (see Fig. 10(b)).

3.3. Effect of Sc and q

Next, the effects of Schmidt number, Sc of the slower diffusing scalar and mixed layer thickness, q are investigated in Fig. 11(a) and (b), respectively. Unlike the DD instability

Figure 10: The neutral stability curves for different values of R_1 (solid lines: $\beta = 0$, dashed lines: $\beta = 1$): (a) $R_s = 1$, $R_f = -1.1$, and (b) $R_s = -1.1$, $R_f = 1$. The rest of the parameter values are $Sc = 10$, $q = 0.1$ and $\delta = 10$.

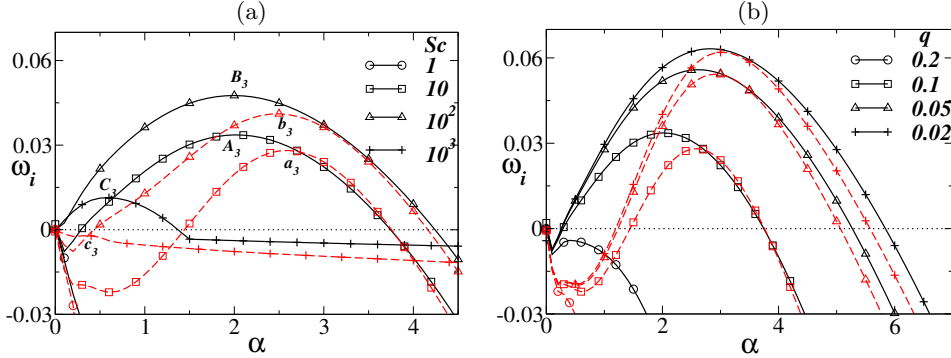

Figure 11: The effect of varying (a) Sc for $q = 0.1$, and (b) q for $Sc = 10$, on the dispersion curves (ω_i versus α). Here, solid and dashed lines represent the results for $\beta = 0$ and $\beta = 1$, respectively. The radius of the center of the mixed region, i.e. $R_1 + q/2$ is fixed at 0.5. The rest of the parameter values are $Re = 500$, $R_s = 1$, $R_f = -1.1$ and $\delta = 10$. The region above the dotted line ($\omega_i = 0$) is the unstable region. The points A_3 , B_3 , C_3 and a_3 , b_3 , c_3 in panel (a) correspond to the most dangerous axisymmetric and corkscrew modes for $Sc = 10$, 100 and 1000, respectively. The equivalent SC flows ($Sc_{eq} = 2Sc/(\delta + 1)$, $R_s = -0.1$ and $R_f = 0$) are stable ($\omega_i < 0$) for these sets of parameter values.

Table 3: Energy budgets for the points labeled A_3 , B_3 , C_3 , a_3 , b_3 and c_2 in Fig. 11(a).

in planar flow (Sahu & Govindarajan 2011), Schmidt number has a non-monotonic effect in pipe flow for the parameter values considered in this study. A similar behaviour of Sc was previously observed in a two-layer planar SC flow for high viscosity ratio in the Stokes flow regime (Talon & Meiburg 2011). They also suggested a mechanism of this non-monotonic behaviour of Sc using an argument similar to the one proposed by Hinch (1984) for interfacial flows. It can be seen that increasing Sc increases the maximum growth rate of the perturbation and also increases the range of α for which the flow is unstable for both the axisymmetric and corkscrew modes. It can also be seen that for all values of Sc , the faster-growing axisymmetric mode is more unstable than the corresponding corkscrew mode. As expected, in Fig. 11(b), it is found that decreasing the mixed layer thickness, q increases the growth rate.

It is to be noted here that for the parameter values considered so far, the equivalent single component system whose diffusivity is the average of \mathcal{D}_s and \mathcal{D}_f , i.e., $Sc_{eq} = 2Sc/(\delta + 1)$, is linearly stable.

To understand the non-monotonic behaviour of Schmidt number in the DD system, the energy budget analysis is conducted. The contributions of the various energy terms (discussed in the Appendix 1) at points A_3 , B_3 and C_3 (associated with the most dangerous axisymmetric modes for $Sc = 10$, 100 and 1000, respectively) and a_3 , b_3 and c_3 (associated with the most dangerous corkscrew modes for $Sc = 10$, 100 and 1000, respectively) are given in table 3. It can be seen that for the axisymmetric modes, the negative contribution due to the viscous dissipation ($-\mathcal{D}$) almost balances out the positive contribution due to the gradient of viscosity perturbation in the radial direction \mathcal{B}_r , and the non-monotonicity in the stability behaviour is clearly due to the rate of transfer of energy from the basic flow to the perturbation (\mathcal{P}). However, for the corkscrew mode, the mechanism of instability is due to the combined effects of the energy terms. It can also be seen that the values of \mathcal{B}_r for axisymmetric modes are much larger than those for the corresponding corkscrew modes. Thus, the faster-growing axisymmetric modes are more unstable than the corresponding corkscrew modes for this set of parameter values. Finally in this section, the effect of the DD phenomenon on unstable configurations in the context of SC flows, will be investigated.

3.4. Unstable case in the context of SC flows

The stability behaviour of the DD systems in the unstable regions for which the net viscosity stratifications are positive ($R_s + R_f > 0$, i.e., when the annular fluid is more viscous than the core fluid) and negative ($R_s + R_f < 0$, i.e., when the annular fluid is less viscous than the core fluid) is investigated in Fig. 12. As discussed above, the axisymmetric mode is dominant for $R_s + R_f < 0$, whereas the corkscrew mode is the most unstable one for $R_s + R_f > 0$. The corresponding results for the equivalent SC system ($Sc_{eq} = 2Sc/(\delta + 1)$, where modified R_s and R_f values are set to $R_s + R_f$ and $R_f = 0$) are also shown by dashed lines. It can be seen that the region of instability and the maximum temporal growth rate are larger in the case of the DD system as compared to the equivalent SC system. The critical Reynolds number obtained for the DD system is also lower than that of the equivalent SC system. This result also demonstrates that the DD effect enhances the instability even in the linearly unstable regions in the context of SC flows.

The results presented so far are obtained from the linear stability analysis. The DD flow in the nonlinear region is discussed in the next section.

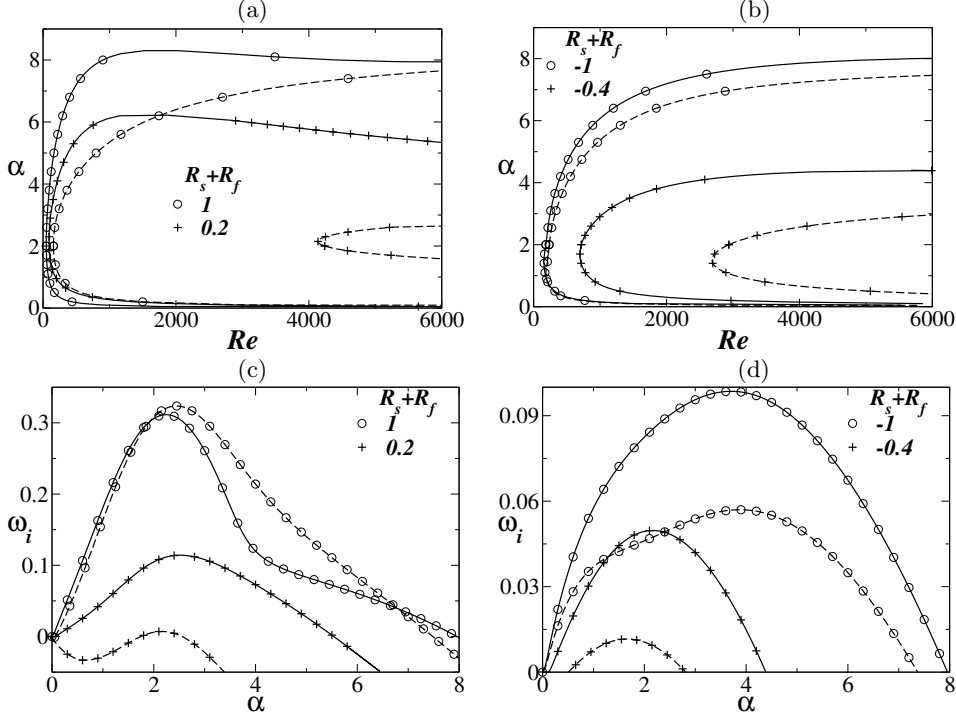

Figure 12: Stability characteristics in the unstable SC regions: (a,c) $R_s + R_f > 0$, (b,d) $R_s + R_f < 0$. The solid and dashed lines represent the results for the DD and the equivalent SC systems, respectively. For the DD system in panel (a) $R_f = -1$, $\beta = 1$, and in panel (b) $R_s = 1$ and $\beta = 0$, and for the single component system ($Sc_{eq} = 2Sc/(\delta + 1)$, modified R_s and R_f values are set to $R_s + R_f$ and $R_f = 0$), respectively. The rest of the parameter values are $R_1 = 0.45$, $q = 0.1$ and $\delta = 10$.

4. Direct numerical simulations

As axisymmetric modes are found to be the most unstable eigenmodes by the linear stability analysis, in this section, axisymmetric numerical simulations are conducted by solving Eqs. (2.7)-(2.10) directly without further assumptions using the no-slip and the no-penetration boundary conditions for the velocity components and the no-flux conditions for the scalars s and f at the pipe wall. A periodic boundary condition is implemented in the axial direction. A bespoke finite-volume flow solver (Sahu *et al.* 2009; Tripathi *et al.* 2015) is used to solve the governing equations on a staggered grid. The scalar variables (the pressure and the volume fraction of the outer fluid) are defined at the cell-centres and the velocity components are defined at the cell faces, respectively. In order to achieve second-order accuracy, the Adams-Bashforth and the Crank-Nicholson methods are used to discretize the advective and dissipation terms in Eq. (2.8), respectively.

The discretized governing equations are given by:

$$\frac{\mathbf{u}^* - \mathbf{u}^n}{\Delta t} = \frac{1}{p^{n+1/2}} \left\{ - \left[\frac{3}{2} \mathcal{H}(\mathbf{u}^n) - \frac{1}{2} \mathcal{H}(\mathbf{u}^{n-1}) \right] + \frac{1}{2Re} [\mathcal{L}(\mathbf{u}^*, \mu^{n+1}) + \mathcal{L}(\mathbf{u}^n, \mu^n)] \right\}, \quad (4.1)$$

where \mathbf{u}^* is the intermediate velocity, and \mathcal{H} and \mathcal{L} denote the discrete convection and

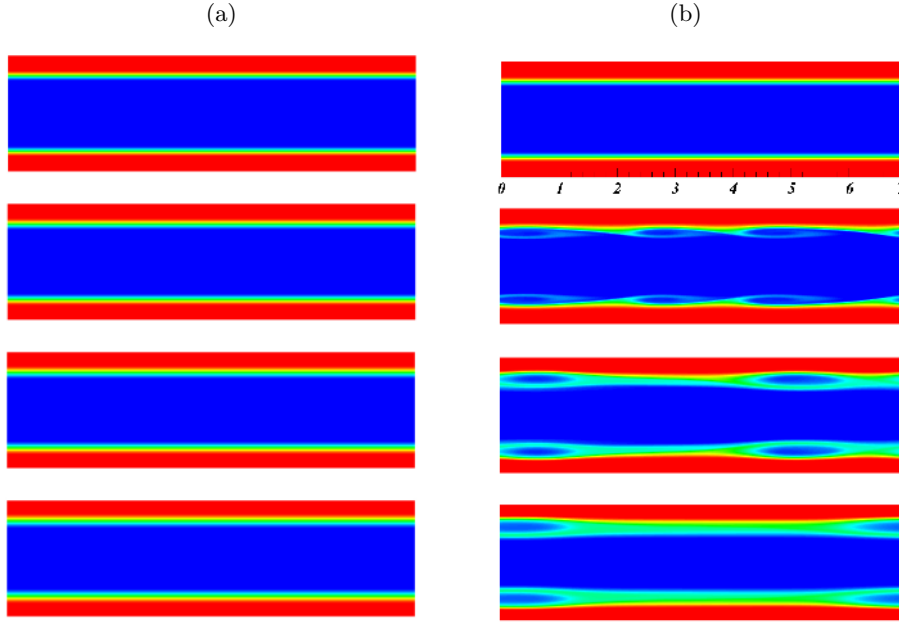

Figure 13: The spatio-temporal evolutions of the s contours: (a) $\delta = 1$ and (b) $\delta = 20$. From top to bottom: $t = 100, 150, 200$ and 250 . The rest of the parameter values are $Re = 1000, Sc = 100, R_s = 1, R_f = -1.1$. The values of R_1 and q at the starting of the simulations are 0.6 and 0.1 , respectively.

Figure 14: The dispersion curve obtained from the linear stability analysis for $\delta = 20$ with the rest of the parameters the same as those used to generate Fig. 13. The phase speed of the most dangerous mode, $c_r(\equiv \omega_{rmax}/\alpha_{max}) = 1.26$.

diffusion operators, respectively. $\Delta t = t^{n+1} - t^n$ and the superscript n signifies the discretized n^{th} step.

The intermediate velocity \mathbf{u}^* is then corrected to $(n+1)^{th}$ time level.

$$\frac{\mathbf{u}^{n+1} - \mathbf{u}^*}{\Delta t} = \nabla p^{n+1/2}. \quad (4.2)$$

The pressure distribution is obtained from the continuity equation at time step $n+1$

using

$$\nabla \cdot (\nabla p^{n+1/2}) = \frac{\nabla \cdot \mathbf{u}^*}{\Delta t}. \quad (4.3)$$

The discretized diffusion equations of the slower and faster diffusing species are

$$\frac{\frac{3}{2}s^{n+1} - 2s^n + \frac{1}{2}s^{n-1}}{\Delta t} = \frac{1}{ReSc} \nabla^2 s^{n+1} - 2\nabla \cdot (\mathbf{u}^n s^n) + \nabla \cdot (\mathbf{u}^{n-1} s^{n-1}), \quad (4.4)$$

$$\frac{\frac{3}{2}f^{n+1} - 2f^n + \frac{1}{2}f^{n-1}}{\Delta t} = \frac{\delta}{ReSc} \nabla^2 f^{n+1} - 2\nabla \cdot (\mathbf{u}^n f^n) + \nabla \cdot (\mathbf{u}^{n-1} f^{n-1}), \quad (4.5)$$

respectively. Here, the weighted-essentially-non-oscillatory (WENO), and central difference schemes are used to discretize the advective and diffusive terms in Eqs. (2.9) and (2.10), respectively.

The results obtained from this solver are validated against another finite-volume open source code, *Gerris* (Popinet 2003; Tripathi *et al.* 2015) with dynamic adaptive grid refinement feature based on the vorticity magnitude and species concentration. We found that the finest grid size of 0.015 (approximately) in the diffusive region of the slower and faster diffusing species and grids of size 0.06 (approximately) in the vortical region are sufficient to yield grid independent results to capture the onset of instability and other flow features for the parameters considered in the present study. The readers are referred to Tripathi *et al.* (2015) for detailed description of the numerical method used in this study.

The objective of this section is to demonstrate the appearance of DD instability in the nonlinear regime for $\delta > 1$. It can be seen in figure 13 that the flow is unstable giving rise to “roll-up” structures (Kelvin-Helmholtz (KH) type instability) in the presence of DD effect ($\delta = 20$), whereas the flow is completely stable for $\delta = 1$. The rest of the parameter values are $Re = 1000$, $Sc = 100$, $R_s = 1$, $R_f = -1.1$, $R_1 = 0.6$ and $q = 0.1$. It can be seen that for $t \geq 200$, a new type of instability of an elliptical shape is observed, which migrates at a speed close to the phase speed of the most dangerous mode for this set of parameters. It is found (not shown) that although at $t = 0$ the less (high) viscous fluid occupies the annular (core) region of the pipe, the double-diffusive phenomenon alters the viscosity variation at the later times by creating a highly viscous region near the wall, which is the main cause of instability observed in this case. A similar mechanism was previously observed by Mishra *et al.* (2012) and Bhagat *et al.* (2016) in the numerical simulations of displacement flows in planar channel and axisymmetric pipe in the presence of DD effect. On the other hand the dynamics for $\delta = 1$ is dominated only by diffusive mixing. The wavelength ($2\pi/\alpha$) of the most dangerous mode obtained from the linear stability analysis (shown in Fig. 14) is approximately equal to that obtained in the nonlinear simulation for $\delta = 20$. This also confirms the finding of the linear stability analysis conducted in the previous section.

5. Concluding remarks

The instability due to the double-diffusive effect in a core-annular pipe flow of two miscible fluids of the same densities, but different viscosities is investigated using linear stability theory and direct numerical simulations. The DD flow exhibits strikingly different stability characteristics as compared to the DD flow in a planar channel and the corresponding SC flow in a cylindrical pipe. The flow which is stable in the context of SC systems, now becomes unstable in the presence of two scalars diffusing at different rates. It is found that increasing the diffusivity ratio of the faster and the slower diffusing scalars

enhances the instability by increasing the growth rate of the perturbation, and also by widening the unstable region. In contrast with the single fluid flow through a pipe (the Hagen-Poiseuille flow), it is shown that the faster growing axisymmetric mode is more unstable than the corresponding corkscrew mode for the parameter values considered. The equivalent SC flows are stable to all the modes (for any value of β). However, this finding is consistent with that of Selvam *et al.* (2007) for SC core-annular flow, who found that beyond a critical viscosity ratio, when the annular fluid is less viscous than the core fluid, the axisymmetric mode is the most unstable one. It is found that Schmidt number (Sc) and the radial location of the mixed layer (R_1) have non-monotonic influences on the instability characteristics, and as expected, decreasing the mixed layer thickness increases the growth rate.

An energy budget analysis is conducted in order to understand the underlying mechanism of the instability in the DD flow, whose equivalent SC system is stable. It is found that the ‘‘Reynolds stress’’ term, which represents the rate of transfer of energy from the basic flow to the perturbations and rate of energy associated with the gradient of viscosity perturbations in the radial direction provide positive contributions to the DD instability observed in this work. The inviscid stability theory conducted in this study shows that the DD flows in a cylindrical pipe are inviscidly stable. Thus, the neutral stability curves are closed curves at high Re .

The direct numerical simulations conducted for different diffusivity ratios, δ , show the development of the DD instabilities in the nonlinear regime. The behaviour observed in direct numerical simulations is consistent with that obtained from the linear stability theory; the wavelengths of the unstable waves observed in the numerical simulation and the linear stability theory are found to be approximately the same. A new type of instability pattern of an elliptical shape is observed in the nonlinear simulations in the presence of double-diffusive effect. In some flows, such as flow in vertical pipes and in configurations where inertial force is much larger than the gravitational force, buoyancy variations could be negligible, and the present study will be directly relevant to such situations. However, including the density variation will make the problem more complex due to the simultaneous interplay between the viscosity and density stratifications. It is hoped that the present work will motivate experiments on double-diffusive systems with viscosity stratification to confirm the findings.

Appendix 1: Energy budget analysis

In order to gain insight into the mechanisms underlying the instabilities, we have carried out an energy budget analysis; a similar analysis was also performed by Selvam *et al.* (2007) and Sahu *et al.* (2009) for single-component miscible flows in a pipe and a two-dimensional channel, respectively. The energy equation is derived by multiplying Eqs. (2.18), (2.19) and (2.20) with the radial, azimuthal and axial components of the perturbation velocity, respectively. By adding the resulting equations and integrating across the domain, we obtain the require energy budget equation, given by

$$\dot{\mathcal{E}} = \mathcal{P} - \mathcal{D} + \mathcal{A} + \mathcal{B} + \mathcal{C}, \quad (5.1)$$

where

$$\dot{\mathcal{E}} = \int_0^1 \dot{E} r dr = \omega_i \int_0^1 (u_r u_r^* + u_\theta u_\theta^* + u_z u_z^*) r dr, \quad (5.2)$$

$$\mathcal{P} = \int_0^1 P_d r dr = \int_0^1 \text{Imag} (u_r u_z^*) U'_z r dr, \quad (5.3)$$

$$\mathcal{D} = \int_0^1 D r dr = \frac{1}{Re} \int_0^1 \mu_0 \left[u_r' u_r'^* + u_\theta' u_\theta'^* + u_z' u_z'^* + \left(\frac{\beta^2}{r^2} + \alpha^2 \right) (u_r u_r^* + u_\theta u_\theta^* + u_z u_z^*) + \frac{1}{r^2} \{ u_r u_r^* + u_\theta u_\theta^* + 4\beta \text{Real}(u_\theta u_r^*) \} \right] r dr, \quad (5.4)$$

$$\mathcal{A} = \int_0^1 A r dr = \frac{1}{Re} \int_0^1 \frac{\mu_0'}{r} \left(\frac{d}{dr} (r u_r u_r^*) - u_\theta u_\theta^* \right) r dr, \quad (5.5)$$

$$\begin{aligned} \mathcal{B} &= \mathcal{B}_r + \mathcal{B}_z = \int_0^1 B_r r dr + \int_0^1 B_z r dr = \\ &= \frac{1}{Re} \int_0^1 U_z' \text{Real}(\mu' z^*) r dr + \frac{1}{Re} \int_0^1 U_z' \text{Real}(\alpha \mu u_r^*) r dr, \end{aligned} \quad (5.6)$$

$$\mathcal{C} = \int_0^1 C r dr = \frac{dP}{dz} \int_0^1 \text{Real}(\mu u_z^*) r dr. \quad (5.7)$$

Here $\dot{\mathcal{E}}$ represents the temporal rate of change of the perturbation kinetic energy (for unstable flows, $\dot{\mathcal{E}}$ is positive); \mathcal{P} denotes the ‘‘Reynolds stress’’ term, which determines the rate of transfer of energy from the basic flow to the perturbations, and \mathcal{D} corresponds to the viscous dissipation of energy of the perturbation. The term \mathcal{A} denotes the energy of the perturbations due to mean viscosity gradients. The terms \mathcal{B} and \mathcal{C} are the perturbation energies due to the gradient of viscosity perturbations and viscosity perturbations, respectively. The term \mathcal{B} can be further decomposed into $calB_r$ and \mathcal{B}_z , where \mathcal{B}_r and \mathcal{B}_z are the perturbation energies associated with the gradient of viscosity perturbations in the radial and axial directions, respectively.

Appendix 2: Inviscid stability analysis

The necessary conditions for instability in the inviscid limit ($Re \rightarrow \infty$) states that it is necessary to have a point of inflection in the velocity profile for the two dimensional flow to be inviscidly unstable. This is known as the Rayleigh theorem for inviscid instability in a two-dimensional channel (Rayleigh 1880). The corresponding condition for a pipe flow can be derived from Eqs. (2.17)-(2.20) in the limit $Re \rightarrow \infty$ (Sahu & Govindarajan 2005). The stability equations (Eqs. (2.17)-(2.20)) in the cylindrical coordinate systems in the limit $Re \rightarrow \infty$ are given by

$$\alpha u_z + u_r' + \frac{u_r}{r} + \frac{1}{r} \beta u_\theta = 0, \quad (5.1)$$

$$-\alpha c u_r + U_z \alpha u_r = -p', \quad (5.2)$$

$$-\alpha c u_\theta + U_z \alpha u_\theta = -\frac{\beta p}{r}, \quad (5.3)$$

$$-\alpha c u_z + U_z \alpha u_z + u_r U_z' = -p\alpha. \quad (5.4)$$

Eliminating u_θ , u_z and p from the above equations, we get

$$\begin{aligned} (U_z - c) \left[u_r'' + \frac{(3\beta^2 + \alpha^2 r^2)}{(\alpha^2 r^2 + \beta^2)} \frac{u_r'}{r} - \frac{(\alpha^2 r^2 + \beta^2 + 2)}{(\alpha^2 r^2 + \beta^2)} \alpha^2 u_r + (1 - \beta^2) \frac{u_r}{r^2} \right] - \\ \left[U_z'' - \frac{(\alpha^2 r^2 - \beta^2)}{r(\alpha^2 r^2 + \beta^2)} U_z' \right] u_r = 0. \end{aligned} \quad (5.5)$$

Let us define a function $f(r)$, which is given by

$$\frac{f'}{f} = \left[\frac{3\beta^2 + \alpha^2 r^2}{r(\alpha^2 r^2 + \beta^2)} \right]. \quad (5.6)$$

Now multiplying Eq. (5.5) with $f(r)u_r^*$ and integrating from $r = 0$ to $r = 1$, we obtain

$$\begin{aligned} \int_0^1 (f u_r')' u_r^* dr - \int_0^1 f \left[\frac{\alpha^2 r^2 + \beta^2 + 2}{\alpha^2 r^2 + \beta^2} \right] \alpha^2 |u_r|^2 dr + \int_0^1 (1 - \beta^2) \frac{|u_r|^2}{r^2} dr = \\ \int_0^1 f \left[U_z'' - \frac{\alpha^2 r^2 - \beta^2}{r(\alpha^2 r^2 + \beta^2)} U_z' \right] \frac{|u_r|^2}{|U_z - c|^2} (U_z - c)^* dr, \end{aligned} \quad (5.7)$$

where, superscript * denotes complex conjugate quantities. Integrating the first term in Eq. (5.7) and applying the boundary conditions, we get

$$\int_0^1 (f u_r')' u_r^* dr = f u_r^* u_r' \Big|_0^1 - \int_0^1 f |u_r'|^2 dr = - \int_0^1 f |u_r'|^2 dr. \quad (5.8)$$

As f is always positive (see Eq. (5.6)), it can be shown that for any values of β , the left hand side of Eq. (5.7) is real and negative.

Thus, equating the imaginary part of the Eq. (5.7), we get

$$c_i \int_0^1 f \left[U_z'' - \frac{(\alpha^2 r^2 - \beta^2)}{r(\alpha^2 r^2 + \beta^2)} U_z' \right] \frac{|u_r|^2}{|U_z - c|^2} dr = 0, \quad (5.9)$$

where c_i is the imaginary part of the phase speed, c . For unstable flow $c_i > 0$, hence

$$\int_0^1 f I \frac{|u_r|^2}{|U_z - c|^2} dr = 0, \quad (5.10)$$

where

$$I \equiv U_z'' - \frac{(\alpha^2 r^2 - \beta^2)}{r(\alpha^2 r^2 + \beta^2)} U_z'. \quad (5.11)$$

Therefore, a necessary condition of instability for pipe flow is the quantity $I = 0$ at some radial location inside the pipe.

Appendix 3: Parallel flow assumption

Consider a situation when a splitter plate is located at $z < z_0$, at a constant r and the parallel streams of two miscible fluids flow on both sides of this plate. The streams come in to contact with each other at $z = z_0$. The two fluids begin to mix with each other for $z > z_0$, thus producing a stratified layer. The thickness 'q' of this layer grows as the fluids move downstream and therefore q is a function of z .

We know at any location, the mean concentrations f_0 and s_0 corresponding to the species F and S satisfy

$$\frac{\partial f_0}{\partial t} + \mathbf{u} \cdot \nabla f_0 = \frac{\delta}{ReSc} \nabla^2 f_0, \quad (5.1)$$

$$\frac{\partial s_0}{\partial t} + \mathbf{u} \cdot \nabla s_0 = \frac{1}{ReSc} \nabla^2 s_0, \quad (5.2)$$

respectively. For slow diffusion (i.e for high $Pe \equiv ReSc$), we can make the assumption of locally parallel flow (variations of f_0 and s_0 in the r direction are much larger than that in the axial direction); thus ($u_r \ll u_z$ and $\frac{\partial^2}{\partial z^2} \ll \frac{\partial^2}{\partial r^2}$). This is equivalent to saying

that the variations of the gradients of the flow variables and the thickness q of the mixed region have much larger length scale than the disturbance wavelength. In such a scenario, the concentrations are function of r and t only and not of z . Thus the above equations reduce to

$$\frac{\partial f_0}{\partial t} = \frac{1}{Pe} \frac{\partial^2 f_0}{\partial r^2}, \quad (5.3)$$

and

$$\frac{\partial s_0}{\partial t} = \frac{1}{Pe} \frac{\partial^2 s_0}{\partial r^2}. \quad (5.4)$$

Also, using the same approximation, we know that $U \sim O(1)$, $r \sim \sqrt{\nu}$, where ν is the kinematic viscosity. Therefore, $qf_0 \sim O(r^2)$ since f_0 is the mean concentration over the mixed layer of thickness q . This implies that $\partial f_0/\partial z \simeq \frac{1}{q} O(\delta/Pe)$ (from Eq. (5.3)). Similarly, from Eq. (5.4), we can get $\partial s_0/\partial z \simeq \frac{1}{q} O(1/Pe)$. So, for large values of Pe , $\partial f_0/\partial z$, $\partial s_0/\partial z$ are very small, showing that the downstream variation of f_0 and s_0 are very small, which in turn implies that the changes in the thickness q of the mixed layer along the z -direction is very small.

Alternatively, if we assume a similarity solution $f_0(r/q(z)) \simeq f(\zeta)$ (where $\zeta = (r/q(z))$), from Eq. (5.1), at the steady state, we get

$$u_z \frac{df_0}{d\zeta} \left(-\frac{\zeta}{q} \frac{dq}{dz} \right) \simeq \frac{\delta}{Pe} \left(\frac{d^2 f_0}{d\zeta^2} \frac{1}{q^2} \right). \quad (5.5)$$

As a consequence,

$$\frac{1}{q} \frac{dq}{dz} \sim \frac{\delta}{q^2 Pe} \Rightarrow \frac{dq}{dz} \sim \frac{1}{q} O\left(\frac{\delta}{Pe}\right). \quad (5.6)$$

Thus, the downstream growth of mixed layer is inversely proportional to the Péclet number as u_r and ζ are of $O(1)$ and $O\left(\frac{df_0}{d\zeta}\right) \simeq O\left(\frac{d^2 f_0}{d\zeta^2}\right)$, which confirms that for the Reynolds and Schmidt numbers considered in the present study, the assumption of uniform thickness of viscosity stratified layer (mixed layer) is justified.

Now, the solution of Eq. (5.3) or Eq. (5.4) is an error function, and the fifth order polynomial is a good representation of this. We also note here that such basic flows are commonly used in stability studies. Several authors have used the same logic to give a basic concentration profile in the form of a hyperbolic tangent (Ern *et al.* 2003) or an error function (e.g. Selvam *et al.* (2007); Talon & Meiburg (2011)). Some have also used a fifth-order polynomial (see e.g. Malik & Hooper (2005); Sahu *et al.* (2009)), which is smooth enough to approximate either profile.

Acknowledgement

The author gratefully acknowledged Prof. Melepurath Deepa of IIT Hyderabad for reading the manuscript and providing valuable suggestions. I also thank Dr. Manoj Tripathi for his help in nonlinear simulations using *Gerris*.
